Beyond Kappa: Estimating Inter-Rater Agreement with Nominal Classifications

Nol Bendermacher  Pierre Souren
Radboud University
Nijmegen, The Netherlands

Cohen’s Kappa and a number of related measures can all be criticized for their definition of correction for chance agreement. A measure is introduced that derives the corrected proportion of agreement directly from the data, thereby overcoming objections to Kappa and its related measures.

Key words: Interrater agreement, Cohen’s Kappa, nominal data, reliability.

Introduction

The most popular measure of inter-rater agreement in the case of nominal classification is Cohen’s kappa (Cohen, 1960). Kappa is a member of a family of measures that are all defined by the same basic formula (Zwick, 1988):

\[
A = \frac{f - p_c(A)}{1 - p_c(A)}
\]  (1.1)

where \(f\) = the observed proportion of agreement and \(p_c(A)\) = the definition of chance agreement according to measure A. The measures of this family differ only in their definitions of chance agreement \(p_c(A)\).

Methodology

A General Model

Starting with \(n\) cases classified by two raters into \(c\) exhaustive and mutually exclusive categories, the population distribution of the \(c\) categories is given by the vector \(V\). The joint distribution of the ratings is given by the \(c\) by \(c\) population matrix \(X\). The model distinguishes three types of classifications: (1) a correct observation, (2) a correct guess, and (3) a wrong guess. The second type is a correct classification, but not a correct observation. The model assumes a fixed probability \(p_r\) that rater \(r\) makes a correct observation, i.e., a classification of type (1). Fixed means that \(p_i\) is independent of the true category \(V_i\) of the case and of its classification by the other rater. Rater agreement, as far as it is not based on chance, arises if both raters make a correct observation. Assuming that raters act independently, the probability of such non-chance-agreement is \(p_1p_2\). Therefore a measure of inter-rater agreement is defined as: \(s = p_1p_2\).

If rater \(r\) performs a correct observation, the probabilities of the categories are given by the population distribution \(V\). However, if the rater does not, the classifications follow an error distribution \(W_r\). The error distributions may differ from \(V\) and from each other. It is assumed that \(W_r\) is independent of the true category of the case. The model parameters are \(p_1, p_2, V, W_1\) and \(W_2\) as defined above. In order to simplify the formulas \(q_r = 1 - p_r\) and \(D_r = W_r - V\) are also defined. This article will show that \(s\) and \(V\) can be estimated directly from the observed sample of classifications by the raters, without any assumptions regarding the error distributions \(W_1\) and \(W_2\).
Some Measures for Inter-rater Agreement

In formula (1.1), \( f \) is the proportion of cases classified in the same way by both raters, and \( p_c(A) \) is the correction for chance agreement according to measure \( A \). The denominator is a scaling factor restricting the measure to a maximum of 1.

Bennett, Alpert and Goldstein (1954) assumed that a rater who does not recognize the true category of a case draws from a uniform distribution, thus giving each category an equal chance. In terms of the general model, they assume \( W_1 = W_2 = \left( \frac{1}{c}, \frac{1}{c}, \ldots, \frac{1}{c} \right)^T \). If both raters draw from this common error distribution, the probability of chance agreement on one specific category is \( \frac{1}{c^2} \) and the overall expected proportion of chance agreement is \( \frac{c}{c^2} = \frac{1}{c} \).

Therefore, Bennett, Alpert and Goldstein (1954) defined the correction for chance agreement as

\[
p_c(A) = \frac{1}{c} \quad \text{for their measure } S.
\]

At least two objections to this choice exist:

1. In many situations it is plausible that the true distribution \( V \) of the cases deviates from uniformity and that the raters, knowing so, adjust their guessing distributions accordingly.

2. Scott (1955) objected that if \( W_1 \) and/or \( W_2 \) deviate from uniformity, the proportion of agreement by chance will always be greater than \( \frac{1}{c} \). In other words, \( \frac{1}{c} \) is a lower limit for the proportion of agreement by chance, meaning that \( S \) is an upper bound for inter-rater agreement.

\( S \) has been presented several times under different names and different notations. For the case of two categories \( S \) is equal to the random error \( RE \) (Maxwell, 1977). With only two categories, this measure is equal to the difference between the proportion of agreement and the proportion of disagreement: \( f = \frac{f}{1-f} \). For the general case, Brennan and Prediger (1981) reported the measure as \( \kappa \), Zwick (1988) mentioned Guilford’s \( G \), for the two categories case, and Janson and Vegelius’ \( C \) for the general case.

Scott (1955) tried to overcome the second objection by introducing the assumption that both raters, when guessing, follow the true distribution. In terms of the general model, Scott assumed that \( W_1 = W_2 = V \). Therefore he estimated the distribution by the average of the two marginal distributions. His measure is called \( \pi \) and \( p_c(\pi) \) is defined as

\[
\sum_{i=1}^{c} \left( \frac{M_{1i} + M_{2i}}{2i} \right)^2,
\]

where \( M_{1i} \) and \( M_{2i} \) are the two observed marginal proportions of category \( i \).

Cohen (1960) objected to Scott that one source of disagreement is precisely the tendency of the raters to spread their ratings differently over the categories: "one source of disagreement between a pair of judges is precisely their proclivity to distribute their judgments differently over the categories." Therefore, Cohen dropped the assumption of equal marginal distributions and defined the proportion of chance agreement as

\[
\sum_{i=1}^{c} M_{1i} M_{2i}.
\]

It can be seen, however, that the marginal distributions are a mix of the true distribution \( V \) and the error distributions \( W_1 \) and \( W_2 \), more precisely, \( M_r = p_r V + q_r W_r \), so Cohen’s estimation of chance agreement is only correct under the null hypothesis that \( p_1 \) and \( p_2 \) are both zero, or under the assumption that \( W_1 = W_2 = V \). The latter assumption would mean that the two marginal distributions are equal, so Scott’s \( \pi \) could be used as well. As Brennan and Prediger (1981) stated: “For descriptive purposes, therefore, when marginals are free it seems questionable to reduce observed agreement by \( \sum P_i P_i \), which is directly dependent on agreement in the marginals” (p. 692). Other objections and alternatives to Kappa have also been brought forward. For details, readers are referred to Perreault and Leigh (1989) and Brennan and Prediger (1981).

The next section will elaborate on the formal model and investigate possibilities to identify and estimate the model parameters.
What is special to this approach is that the inter-rater agreement is estimated without any assumptions regarding the rater distributions \( W_1 \) and \( W_2 \). In addition, a short outline of an algorithm that performs the required calculations is provided and an extension for the case of three simultaneous raters is introduced. Two computer programs, called Raters2 and Raters3, that implement these ideas are available at http://www.ru.nl/socialewetenschappen/rto/g/software/statistische/kunst/.

Table 1 shows the two-way frequency distribution and the corresponding proportions, Cohen (1960, p. 45) used as an illustration. The proportion of joint judgments is the sum of the diagonal cells, here called \( f \). In this example \( f = 0.70 \). Cohen defined chance agreement as

\[
\sum_{i=1}^{c} M_{1i} M_{2i}.
\]

In the example the correction is \( 0.30 + 0.09 + 0.02 = 0.41 \), so the corrected proportion of joint judgments is:

\[
f - \sum_{i=1}^{c} M_{1i} M_{2i} = 0.29.
\]

If this value is rescaled by dividing it by its maximum, Cohen’s Kappa results:

\[
Kappa = \frac{f - \sum_{i=1}^{c} M_{1i} M_{2i}}{1 - \sum_{i=1}^{c} M_{1i} M_{2i}} = 0.4915 \quad (1.2)
\]

The General Model in Detail

From the model parameters, the population distribution \( X \) of the simultaneous classifications can be derived. Any cell \( X(i,j) \) of \( X \) defines the probability of a joint classification in category \( i \) by rater 1 and category \( j \) by rater 2. \( X \) can be estimated from the two-way frequency matrix of the ratings in the sample, which will be indicated as \( \hat{X} \). \( X \) can be interpreted as a weighted sum of four \( c \) by \( c \) matrices, corresponding to the behavior of the raters:

\( X_1 \): Both raters perform a correct observation. The probability of a score in a diagonal cell \( X_{1ii} \) is the product of: (a) the probability \( V_i \) that the case belongs to category \( i \), (b) the probability \( p_1 \) that rater 1 performs a correct observation and (c) the probability \( p_2 \) that rater 2 performs a correct observation. Thus, \( X_{1ii} = p_1 p_2 V_i \). The probability of a score in an off-diagonal cell is zero, so \( X_1 \) is a diagonal matrix.

\( X_2 \): Only rater 1 performs a correct observation. The probability of a score in a cell \( X_{2ij} \) is the product of: (a) the probability \( V_i \) that the case belongs to category \( i \), (b) the probability \( p_1 \) that rater 1 performs a correct observation, (c) the probability \( q_2 \) that rater 2 guesses, and (d) the probability \( W_2j \) that rater 2 guesses category \( j \). Thus, \( X_{2ij} = p_1 V_i q_2 W_2j \).

\( X_3 \): Only rater 2 performs a correct observation. The probability of a score in a cell \( X_{3ij} \) is the product of: (a) the probability \( V_j \) that the case belongs to category \( j \), (b) the probability \( p_2 \) that rater 2 performs a correct observation, (c) the probability \( q_1 \) that rater 1 guesses and (d) the probability \( W_1i \) that rater 1 guesses category \( i \). Thus, \( X_{3ij} = p_2 V_j q_1 W_1i \).

\( X_4 \): Both raters are guessing. The probability of a score in a cell \( X_{4ij} \) is the product of: (a) the probability \( q_1 \) that rater 1 is guessing, (b) the probability \( q_2 \) that rater 2 is guessing, (c) the probability \( W_1i \) that rater 1 guesses category \( i \) and (d) the probability \( W_2j \) that rater 2 guesses category \( j \). Thus, \( X_{4ij} = q_1 q_2 W_1 i W_2 j \).

The matrix \( X \) is the sum of these 4 matrices and its content can be summarized as follows:

For \( i \neq j \):

\[
X_{ij} = p_1 q_2 V_i W_2 j + q_1 p_2 W_1 i V_j + q_1 q_2 W_1 i W_2 j
= (1 - p_1 p_2) V_i V_j + q_1 V_j D_{1i} + q_2 V_i D_{2j} + q_1 q_2 D_{1i} D_{2j},
\]

and, for \( i = j \):

\[
X_{ii} = p_1 q_2 W_2 i + q_1 p_2 W_1 i
= (1 - p_1 p_2) W_1 i \quad \text{for} \quad i = j.
\]
\[
X_{ii} = p_1p_2V_i + p_1q_2V_iW_{2i} + q_1p_2V_iW_{1i} + q_1q_2W_{1i}W_{2i} = 
\]
\[
p_1p_2V_i + (1-p_1p_2)V_i^2 + q_1V_iD_{1i} + q_2V_iD_{2i} + q_1q_2D_{1i}D_{2i}.
\]

(3)

The marginal distributions \(M_1\) and \(M_2\) of \(X\) are given by:
\[
M_r = p_rV_i + q_rW_i = V_i + q_rD_i, \text{ for } r = 1, 2.
\]

(4)

A similar model is given by Klauer and Batchelder (1996).

Comparing \(s\) to Cohen’s Kappa

The measure \(s\) and Cohen's Kappa can be compared based on the following derivation: from (3) it is evident that
\[
X_{ii} = sV_i(1-V_i) + V_i^2 + q_1V_iD_{1i} + q_2V_iD_{2i} + q_1q_2D_{1i}D_{2i}
\]

and, from (4),
\[
M_{1i}M_{2i} = V_i^2 + q_1V_iD_{1i} + q_2V_iD_{2i} + q_1q_2D_{1i}D_{2i}
\]

thus,
\[
X_{ii} - M_{1i}M_{2i} = sV_i(1-V_i),
\]

(5)

Identifiability of Model Parameters

By the identifiability of the parameters is meant that their values can be uniquely derived from the joint distribution matrix \(X\). If \(B_i = X_{ii} - M_{1i}M_{2i}\), then from (5):
\[
B_i = sV_i(1-V_i)
\]

(6)

With at least 3 non-zero entries in \(V\), the largest entry is the one closest to 0.5. Therefore, it corresponds to the largest entry in \(B\). In other words: if \(B_m\) is (one of) the largest entry(s) in \(B\), \(V_m\) is (one of) the largest entry(s) in \(V\). From (6):
\[
\frac{V_j(1-V_j)}{V_m(1-V_m)} = \frac{B_j}{B_m}
\]

and, as a consequence, for all \(j \neq m\),
\[
V_j = 0.5 \pm \sqrt{0.25 - V_m(1-V_m)\frac{B_j}{B_m}}
\]

Because there can be only one entry in \(V\) greater than 0.5, the sign before the square root must be negative for all \(j \neq m\):
\[ V_j = 0.5 - \sqrt{0.25 - V_m (1 - V_m) \frac{B}{B_m}} \quad (7) \]

It can be proved that there is only one value \( V_m \) for which the sum of elements in \( V \) according to (7) becomes 1, provided that: \( X \) obeys to the model, \( c > 2 \) (and consequently \( V_m < 1 \)), \( s > 0 \), and, by definition, the sum of the elements in \( V \) equals 1. Figure 1 shows an example of the sum \( g(V_m) = V_m + \sum_{j \neq m} V_j \) as a function of \( V_m \) and with \( V_j \) defined by (7).

![Figure 1: Example of the Function g(Vm)](image)

Thus, there is only one vector \( V \) for which equation (7) holds and for which the elements of \( V \) add up to 1. So \( V \) can be identified.

Once \( V \) has been identified, \( s \) can also be derived from (6):

\[ s = \frac{B}{V_i (1 - V_i)} \quad (8) \]

for any \( i \), except those for which \( V_i = 0 \).

Although the product \( p_1 \cdot p_2 \) (i.e., \( s \)) can be identified, it is generally impossible to identify its components \( p_1 \) and \( p_2 \). From (4) it is known that \( q_i D_r = M_r - V \), but looking at formulas (2) and (3) for the cells in \( X \) a multiplication of \( D_r \) by a constant \( h \) can be compensated by dividing \( q_r \) by the same \( h \). Thus, neither \( W_1 \) and \( W_2 \), nor \( p_1 \) and \( p_2 \) can be identified.

The good news is that boundaries can be identified, within which these parameters are enclosed. The boundaries follow from the facts that: all cells of \( V \), \( W_1 \) and \( W_2 \) represent probabilities and therefore must be in the range \([0, 1]\), and that \( V \), \( W_1 \) and \( W_2 \) must add up to 1. Therefore, the following series of restrictions can be derived:

1. \( s \leq p_1 \leq 1 \) and \( s \leq p_2 \leq 1 \).

2. From (4) it is known that
   \[ s \frac{V_i}{M_{2i}} = p_1 \frac{p_2 V_i}{p_2 V_i + q_2 W_{2i}}, \]
   thus,
   \[ s \frac{V_i}{M_{2i}} \leq p_1 \text{ and } p_2 \leq \frac{M_{2i}}{V_i}. \]

3. Similarly, it is known that:
   \[ s \frac{V_i}{M_{1i}} \leq p_2 \text{ and } p_1 \leq \frac{M_{1i}}{V_i}. \]

4. Since all values of \( W_1 \) are between 0 and 1, it is known that:
   \[ q_i (1 - W_{1i}) \geq 0 \]
   \[ \Rightarrow q_i (1 - V_i) - q_i (W_{1i} - V_i) \geq 0 \]
   \[ \Rightarrow p_i (1 - V_i) + q_i (1 - V_i) - q_i (W_{1i} - V_i) \geq p_i (1 - V_i) \]
   \[ \Rightarrow 1 - V_i - q_i (W_{1i} - V_i) \geq p_i \]
   \[ \Rightarrow \frac{1 - M_{1i}}{1 - V_i} \geq p_i, \text{ and consequently:} \]
   \[ s \frac{1 - V_i}{1 - M_{1i}} \leq p_i. \]

5. In the same way the following may be derived:
   \[ \frac{1 - M_{1i}}{1 - V_i} \geq p_1 \text{ and } s \frac{1 - V_i}{1 - M_{1i}} \leq p_2. \]

These restrictions can be summarized by the following boundaries for all \( i \) and \( k \):

\[ p_1, p_2 \leq p_1 \leq 1 \quad (9) \]
\[ p_1, p_2 \leq p_2 \leq 1 \quad (10) \]
If M2i < 1 (and Vi < 1), then:
\[ s \frac{V_i}{M_{2i}} \leq p_1 \leq \frac{M_{1k}}{V_k} \]  (11)

If M1i < 1 (and Vi < 1), then:
\[ s \frac{V_k}{M_{1k}} \leq p_2 \leq \frac{M_{2i}}{V_i} \]  (12)

If M2i < 1 (and Vi < 1), then:
\[ s \frac{1-V_i}{1-M_{2i}} \leq p_1 \leq \frac{1-M_{1k}}{1-V_k} \]  (13)

If M1i < 1 (and Vi < 1), then:
\[ s \frac{1-V_k}{1-M_{1k}} \leq p_2 \leq \frac{1-M_{2i}}{1-V_i} \]  (14)

These formulas are cross-linked: the minimum for p1 in (11) goes together with the maximum p2 in (12) and the maximum for p1 in (11) corresponds to the minimum for p2 in (12). The link comes from the fact that their product must be s. The formulas in (13) and (14) are connected in a similar way.

The limits from (11) through (14) all hinge upon the differences between the true distribution V and the rater error distributions W1 and W2. If W2 = V the lower limit for p1 is s and the maximum for p2 is 1. If W1 = V the lower limit for p2 is s and the maximum for p1 is 1. From these formulas it is also observed that, for categories with V-values close to 0 or 1, even small differences between W1 or W2 and V will impose strong restrictions.

It must be noted that this model cannot be applied if the number of categories is only 2.

Reparametrization

The parameters, as defined to this point, are neither all identifiable, nor are they independent. Wr and pr cannot be identified, only the combination q1D1 = (1-pr)(Wr-V). Therefore, a reparametrization from the original set of parameters to the set \{s, V, q1D1 and q2D2\} is used in the estimations. Moreover, the vector V adds up to 1 and the vectors q1D1 and q2D2 add up to 0, which means that their elements cannot be estimated independent. Therefore, following Klauer and Batchelder (1996) the model is reparametrized again as follows:

\[ A_i^* = \frac{A_i}{1.1 - \sum_{j=1}^{i-1} A_j} \]  for i = 1, c,

where A = V, q1D1 and q2D2 respectively. The last element Ac is dropped. The back-translation to the original parameters is performed by the formula:

\[ A_i = A_i^* \left(1.1 - \sum_{j=1}^{i-1} A_j\right), \]  for i = 1, c

Initial Parameter Estimations: V and s

For the parameter estimations from an observed matrix \( \hat{X} \) one may proceed in two steps. The first step is a procedure directly derived from the model and uses only information from the diagonal and the marginal frequencies of the observed matrix. In the second step a general minimization algorithm is applied to minimize a criterion (for instance, the negative of the likelihood) based on all cells of \( \hat{X} \). This algorithm starts from the estimations produced by the first step.

For the first step define:

\[ g(x) = x + \sum_{j=m}^{c} \left(0.5 - \sqrt{0.25 - x(1-x)\frac{\hat{B}_j}{\hat{B}_m}}\right) \]

with \( \hat{B}_i = \hat{X}_{ii} - \hat{M}_{ii} \hat{M}_{2i} \) and \( \hat{B}_m = \) the largest value in \( \hat{B} \). (Figure 1 shows an example of this function.) From (7) it is clear that \( \hat{V}_m \) can be estimated by the value of x for which g(x) = 1 with 0 < x < 1. Starting with evaluations of g at 1/c and a suitable maximum (for instance \( \hat{f} \)), an estimate of \( \hat{V}_m \) can be found by a simple iteration process using, for example, the bisection method. The remaining elements of V can be estimated by:
\[ \hat{V}_j = 0.5 - \sqrt{0.25 - \hat{V}_m(l - \hat{V}_m) \frac{\hat{B}_j}{B_m}} \] (15)

Once estimates of \( V \) are obtained, \( s \) can be estimated on the base of (8) as:

\[ \hat{s} = \frac{\hat{B}_i}{\hat{V}_i(l - \hat{V}_i)} \text{ for any } i \text{ (unless } \hat{V}_i = 0), \]

or for a combination of the estimates for different \( i \).

However, with sampled data this direct method may easily fail. Therefore a numerically more robust algorithm to find the same initial estimates of \( V \) and \( s \) was designed, called the ping-pong algorithm, a detailed description of which is provided later.

Initial Estimation of \( W_1 \) and \( W_2 \)

Although the parameters \( W_1, W_2, p_1 \) and \( p_2 \) are not identifiable, the inequalities (9) through (14) offer the possibility to set boundaries around them. These boundaries may define a very narrow area, especially for categories that are very frequent or very rare. But unfortunately it is the infrequent categories for which the analysis produces the least reliable estimations. The problem becomes most serious if there are many categories and relatively few observations, i.e., if \( n/c \) is small. If the limits given by (9) through (14) restrict the estimates \( \hat{\rho}_1 \) and \( \hat{\rho}_2 \) to single values, as occurred when Cohen’s example was analyzed, \( W_1 \) and \( W_2 \) can also be estimated using (4) as:

\[ \hat{W}_r = \hat{V} + \frac{1}{q_r} (M_r - \hat{V}) \]

Final Estimations and Model Test

The initial parameter estimates based on the considerations above are based completely on the diagonal and marginal distributions of \( \hat{X} \) disregarding any information in the off-diagonal cells. In the final estimation procedure information from all cells will be used. A criterion is defined for the dissimilarity between the reconstruction \( X^* \) of \( X \) from the parameter estimates and the observed matrix \( \hat{X} \), and a powerful minimization technique like the Davidon-Fletcher-Powell algorithm is used to improve the initial parameter estimates. An attractive criterion is based on the negative of the likelihood ratio with a small adjustment, defined as:

\[ e_{ij} = \text{Max}(X^*_{ij}, \varepsilon) \]

\[ \text{Crit} = \sum_{i=1}^{c} \sum_{j=1}^{c} \hat{X}_{ij} \text{LN} \left( \frac{\hat{X}_{ij}}{e_{ij}} \right) + \text{penalty} \]

The term \( \varepsilon \) is a small value to prevent division by zero and to avoid too exotic values of \( \frac{\hat{X}_{ij}}{e_{ij}} \), for instance \( \varepsilon = 1.0e-20 \). The penalty serves to force the parameters within the restrictions of the model (for instance \( 0 \leq s \leq 1 \)).

The estimation procedure as designed starts with the ping-pong algorithm resulting in estimates \( \hat{V} \) and \( \hat{s} \), after which the reparametrizations and the minimization procedure are applied. When the final parameter estimates are obtained, a model test can be performed based on the test statistic for the likelihood ratio:

\[ \chi^2 = 2.0 (X^* - X) \text{LN} (X^* - X) + \text{penalty} \]

The associated number of degrees of freedom is \( c^2 - 3c + 1 \).

The whole model as described above is based on the assumption that \( s \) is greater than zero. If \( p_1 = 0 \) or \( p_2 = 0 \), the value of any cell \( X_{ij} \) is equal to the product of the corresponding marginal probabilities \( M_{li} \) and \( M_{cj} \), even if \( X_{ij} \) is a diagonal cell. This assumption that \( s > 0 \) may be tested by the statistic \( t = \sum_{i=j=1}^{c} (\hat{X}_{ij} - X_{ij} \varepsilon) \), which is (approximately) distributed as Student’s \( t \) with \( 1 \) degree of freedom. Confidence intervals for the parameters may be constructed by the use of the information matrix or, if the Hessian matrix is singular, by bootstrapping methods.
The Ping-Pong Algorithm

The ping-pong algorithm is designed to simultaneously estimate \( s = p_1p_2 \), and the largest element \( V_m \) in \( V \). Once \( V_m \) is estimated, the entire vector \( V \) can be estimated according to (15). In order to grasp the basic idea of the algorithm, assume that the exact values for \( B \) and \( f \) are known. Then the logic is as follows. Define: \( t_i = \) upper boundary for \( s \) in the \( i \)th iteration, and \( u_i = \) lower boundary for \( V_m \) in the \( i \)th iteration.

1. From (3) \( s \leq f = \frac{c}{\sum_{i=1}^{c} X_{ii}} \), so choose \( t_0 = f \).

2. From (7):
\[
1 = \sum_{i=1}^{c} V_i = \frac{1}{2}(c-1) + V_m - \sum_{j \neq m} \sqrt{\frac{0.25 - V_m (1 - V_m)}{B_j}} \frac{B_j}{B_m}
\]
so, using (8)
\[
V_m = 1 - \frac{1}{2}(c-1) + \sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j}{t_i}}{s}}
\]
and as a consequence:
\[
V_m \leq 1 - \frac{1}{2}(c-1) + \sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j}{t_i}}{s}} \text{ for any step } i
\]

3. From (8): \( s = \frac{B_m}{V_m (1 - V_m)} \), thus
\[
s \leq \frac{B_m}{u_i (1 - u_i)}
\]

Now the following procedure is applied:

1) \( t_0 = f \)
2) \( u_i = 1 - \frac{1}{2}(c-1) + \sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j}{t_i}}{s}} \)
3) \( t_i = \frac{B_m}{u_{i-1} (1 - u_{i-1})} \)
4) Repeat from 2) until convergence is reached.

This algorithm converges to \( t_i = \hat{s} \) and \( u_i = \hat{V}_m \).

When working with the sample estimators \( \hat{B} \) and \( \hat{f} \) it may be necessary to make some corrections during the iteration process:
1. In the iteration process \( t_0 \) may exceed the value \( t_0 = \hat{f} \). In that case, force \( \hat{B}_m \) to \( \hat{f}.u_{i-1}(1 - u_{i-1}) \) and set \( t_i \) equal to \( \hat{f} \). In order to keep the sum of \( \hat{B} \) unchanged, replace the other elements of \( \hat{B} \) according to the following rule:
\[
\hat{B}_i \leftarrow \hat{B} + \left( \hat{B}_m - \hat{B} \right) \frac{\hat{B}_m^* - \hat{B}}{B_m - \hat{B}}
\]
where \( \hat{B} \) is the mean of the \( \hat{B} \)-values, \( \hat{B}_m \) the original estimate of \( B_m \) and \( \hat{B}_m^* \) the corrected estimate.

2. If the estimate \( u_i \) becomes less than \( 1/c \) force it back to \( 1/c \) and adjust the \( B \)-values accordingly:
\[
u_i < \frac{1}{c},
\]
so
\[
1 - \frac{1}{2}(c-1) + \sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j}{t_i}}{s}} < \frac{1}{c}
\]
Adjust the \( B \)-vector by a vector \( B^* \), such that
\[
1 - \frac{1}{2}(c-1) + \sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j}{t_i}}{s}} = \frac{1}{c},
\]
which means that
\[
\sum_{j \neq m} \sqrt{\frac{0.25 - \frac{B_j^*}{t_i}}{s}} = 0.5c + \frac{1}{c} - 1.5
\]
Make the adjustment by taking \( B^* \) such that each term in the summation, except \( B_m^* \), is multiplied by:
\[
a = \frac{0.5c + \frac{1}{c} - 1.5}{\sum_{j \neq m} \sqrt{0.25 - \frac{B_j}{t_i}}} = \frac{0.5c - 1.5 + \frac{1}{c}}{0.5c - 1.5 + u_i}
\]
This is realized by replacing each $B_j$, except $B_m$, by $B_j^* = 0.25t_j(1-a^2) + a^2B_j$.

Three Raters

Under the given model, the expansion to three simultaneous raters is straightforward. Moreover, with three simultaneous raters, all parameters are identifiable if there are at least three categories. The notation must be extended to three $p$-values $p_1$, $p_2$ and $p_3$, three $q$-values $q_1$, $q_2$ and $q_3$, three $W$-vectors $W_1$, $W_2$ and $W_3$, and three marginal distributions $M_1$, $M_2$ and $M_3$. In addition the matrix $X$ will now have three dimensions. The formulas for the probabilities in the cells of $X$ are more complicated: $X_{ijk}$ is the sum of the corresponding cells in eight submatrices as shown in Tables 3a through 3c.

Table 3a: Formulas for Two Parts of the Matrix $X$ in Case of Three Raters

</table>

Submatrix $X_1$ contains those ratings for which all three raters make a correct observation, as indicated by the code ecc, which means correct-correct-correct. The value in cell $i, j, k$ depends on the equality of the three indices as indicated by the column headings. The other submatrices are organized in the same way: $X_2$ contains ratings where raters 1 and 2 made correct observations, but rater three did not (he guessed, correctly or not), indicated by the label cci (correct-correct-incorrect).

</table>
Table 4 shows an example of the three-way distribution in a sample with size 500. The data were generated by random sampling from a theoretical distribution based on the probabilities given in tables 3a-3c, with the following parameters: \( p_1 = 0.5, p_2 = 0.4, p_3 = 0.6, V^T = (0.3,0.5,0.2), W^T_1 = (0.2,0.5,0.3), W^T_2 = (0.3,0.4,0.3), \) and \( W^T_3 = (0.1,0.7,0.2) \). Initial estimations for \( p_1, p_2, p_3, V, W_1, W_2 \) and \( W_3 \) can be derived from the three marginal planes, which can be computed from \( \hat{X} \) by summation over the categories of one rater:

\[
\begin{align*}
X_{12}^{ij} &= \sum_{k=1}^{c} X_{ijk} \\
X_{13}^{ij} &= \sum_{k=1}^{c} X_{ikj} \\
X_{23}^{ij} &= \sum_{k=1}^{c} X_{kij}
\end{align*}
\]

Tables 5, 6 and 7 show these planes for the example in Table 4.

</tr>
</tbody>
</table>

Define:

\[
\begin{align*}
B_{12}^{ij} &= \hat{X}_{12}^{ij} - \hat{M}_{1i} \hat{M}_{2i} \\
B_{13}^{ij} &= \hat{X}_{13}^{ij} - \hat{M}_{1i} \hat{M}_{3i} \\
B_{23}^{ij} &= \hat{X}_{23}^{ij} - \hat{M}_{2i} \hat{M}_{3i}
\end{align*}
\]

In the example above these values are estimated by:

\[
\begin{align*}
\hat{B}_{12}^{T} &= [0.038036, 0.048944, 0.020524] \\
\hat{B}_{13}^{T} &= [0.071676, 0.068720, 0.061708] \\
\hat{B}_{23}^{T} &= [0.046724, 0.061280, 0.047292]
\end{align*}
\]

Because \( B_{12}^{ij} = p_1 p_2 V_i (1 - V_i) \) and analogously \( B_{13}^{ij} = p_1 p_3 V_i (1 - V_i) \) and \( B_{23}^{ij} = p_2 p_3 V_i (1 - V_i) \):

\[
\begin{align*}
\frac{V_j (1 - V_j)}{V_i (1 - V_i)} &= \frac{B_{12}^{ij}}{B_{12}^{i2}} = \frac{B_{13}^{ij}}{B_{13}^{i2}} \\
&= \frac{B_{23}^{ij}}{B_{23}^{i2}} = \frac{B_{12}^{ij} + B_{13}^{ij} + B_{23}^{ij}}{B_{i2}^{12} + B_{i3}^{13} + B_{i2}^{23}} \\
&= \frac{1}{3} \left( \frac{B_{12}^{i2}}{B_{12}^{i2}} + \frac{B_{13}^{i2}}{B_{13}^{i2}} + \frac{B_{23}^{i2}}{B_{23}^{i2}} \right) \\
&= \frac{1}{3} \left( \frac{B_{12}^{i2}}{B_{12}^{i2}} + \frac{B_{13}^{i2}}{B_{13}^{i2}} + \frac{B_{23}^{i2}}{B_{23}^{i2}} \right)
\end{align*}
\]

The largest value \( V_m \) in \( V \) can be estimated by setting it to the value of \( x \) for which the function \( g(x) = 1 \), where \( g \) is defined as:

\[
g(x) = \sqrt{\frac{0.25 - x(1 - x)}{\frac{B_{12}^{i2} + B_{13}^{i2} + B_{23}^{i2}}{B_{i2}^{12} + B_{i3}^{13} + B_{i2}^{23}}}}
\]

or as

\[
g(x) = \sqrt{\frac{0.25 - x(1 - x)}{\frac{1}{3} \left( \frac{B_{12}^{i2}}{B_{12}^{i2}} + \frac{B_{13}^{i2}}{B_{13}^{i2}} + \frac{B_{23}^{i2}}{B_{23}^{i2}} \right)}}
\]
In this function the index \( m \) refers to the largest value (or one of the largest values) in the \( B \)-vectors. Because the three estimated \( B \)-vectors in a sample may have different orders, choose \( m \) as the index for which

\[
\hat{B}_{m}^{12} + \hat{B}_{m}^{13} + \hat{B}_{m}^{23} \geq \hat{B}_{i}^{12} + \hat{B}_{i}^{13} + \hat{B}_{i}^{23}
\]

for all \( i \). In the example, from (15), \( \hat{V}_{m} = 0.422659 \).

From (14) follows that, for the other elements of \( V \),

\[
V_{j} = 0.5 - \sqrt{0.25 - V_{m}(1 - V_{m}) \left( \frac{\hat{B}_{j}^{12} + \hat{B}_{j}^{13} + \hat{B}_{j}^{23}}{\hat{B}_{m}^{12} + \hat{B}_{m}^{13} + \hat{B}_{m}^{23}} \right)}
\]

and it is found that:

\[
\hat{V}^{T} = [0.348216, 0.422659, 0.229124]
\]

Once the initial estimate of \( V \) is made, the parameters \( p_{1}, p_{2} \) and \( p_{3} \) can be estimated in the following way: from (8) it is known that, for all \( i \),

\[
s_{12}^{12} = p_{1}p_{2} = \frac{B_{i}^{12}}{V_{i}(1 - V_{i})},
\]

so the product can be estimated by averaging over \( i \)-values:

\[
s_{12} = \frac{1}{c} \sum_{i=1}^{c} \hat{V}_{i} \left( 1 - \hat{V}_{i} \right).
\]

In the same way \( s_{13}^{13} \) and \( s_{23}^{13} \) can be estimated and estimates of the parameters \( p_{1}, p_{2} \) and \( p_{3} \) can be found by combining the three estimated \( s \)-values. For any triple \( (i, j, k) \) raters:

\[
s_{ij}^{ik} = \frac{p_{i}p_{j}p_{k}p_{i}}{p_{j}p_{k}} = p_{i}^{2},
\]

so the \( p \)-values can be estimated from their estimated products:

\[
\hat{p}_{i} = \sqrt{\frac{s_{ij}^{ik}}{s_{ik}^{ik}}}
\]

In the example: \( \hat{s}_{12}^{12} = 0.176141, \hat{s}_{13}^{13} = 0.315598, \hat{s}_{23}^{13} = 0.241583 \) and \( \hat{p}_{1} = 0.479694, \hat{p}_{2} = 0.367195, \hat{p}_{3} = 0.657915 \). Once initial estimates for \( V \) and the \( p \)-parameters are obtained, the estimation of the \( W \)-vectors is straightforward. From (4), it is known that, for rater \( r \), \( M_{r} = p_{r}V + (1-p_{r})W_{r} \), so \( W_{r} \) can be estimated by:

\[
W_{r} = \frac{1}{1 - \hat{p}_{r}} \left( M_{r} - \hat{p}_{r} \hat{V} \right).
\]

In the example this results in the following initial estimates:

\[
\hat{W}_{1}^{T} = [0.244016, 0.548241, 0.207744],
\]
\[
\hat{W}_{2}^{T} = [0.281504, 0.405815, 0.312682],
\]
\[
\hat{W}_{3}^{T} = [0.049413, 0.824141, 0.126448],
\]

but with sample data these formulas may lead to negative entries in the estimated \( W \)-vectors. If that occurs the initial estimate for the \( W \)-vector at hand can be set equal to the estimated \( V \).

Final estimates, using information from all cells in \( X \), can be computed by methods analogous to those described, minimizing the adjusted likelihood ratio.

Conclusion

When Cohen (1960) introduced his measure Kappa, he provided a good index to estimate inter-rater agreement in the case of a nominal category system that could be easily computed by hand. Cohen argued that differences in the marginal distributions must be taken into account, but, as shown, his measure Kappa does so correctly only if the marginal distributions are equal. For practical reasons, especially the fact that computers were mostly unavailable in 1960, Kappa could be considered the best available instrument at the time, but with modern computers advancements can be made. A model based on Cohen’s ideas and a procedure to correctly estimate its parameters was presented herein. The model allows - to a certain extent - to separately estimate the qualities of two raters by giving two measures \( p_{1} \) and \( p_{2} \). It also breaks
apart the rater characteristics \((W_1 \text{ and } W_2)\) on one hand and the true distribution of the categories \((V)\) on the other.

If the estimates \(p_r\) and \(W_r\) are truly independent from the distribution \(V\), it becomes possible first to assess these statistics for one rater (using a second rater) in a pilot study, and then to use them in order to find boundaries for the \(V\)-values in the main study without the need for a second rater. The formula to be used follows from (4): 

\[
\hat{V}_i = \frac{M_{ni} - \hat{q}_i \hat{W}_{ni}}{\hat{P}_r}.
\]
